Supporting Information

**ABSTRACT:** The search for highly conducting  $\text{Li}^+$  solid electrolytes focuses on sulfide- and halide-based materials, where typically the strongly atomic disordered materials are the most promising. The atomic disorder corresponds to a flattened energy landscape having similar relative site energies for different  $\text{Li}^+$  positions facilitating motion. In addition, the highly disordered  $\text{Li}^+$  conductors have negligible defect formation energy as moving charges are readily available. This work investigates the isovalent  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  ( $0 \leq x \leq 0.5$ ) and the aliovalent  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  ( $0 \leq x \leq 0.2$ ) substitution series of thio-LISICON materials by using X-ray diffraction, high-resolution neutron diffraction, impedance spectroscopy, and defect calculations. The starting composition  $\text{Li}_3\text{SbS}_4$  has a low ionic conductivity of  $\sim 10^{-11} \text{ S}\cdot\text{cm}^{-1}$  and both substituents improve the ionic conductivity strongly by up to 4 orders of magnitude. On the one hand, in substituted  $\text{Li}_3\text{SbS}_4$  structures, only minor structural changes are observed which cannot sufficiently explain the significant impact on the  $\text{Li}^+$  conductivity. On the other hand, the  $\text{Li}^+$  carrier density reveals a correlation to the activation energy and first-principles defect calculations, displaying significantly reduced defect formation energy upon substitution. Here, we show within two different substitution series that the defect formation energy plays a major role for ionic motion in this class of thio-LISICON materials.

**KEYWORDS:** thio-LISICON, solid electrolyte, defect formation energy, aliovalent substitution, isovalent substitution, impedance spectroscopy

## 1. INTRODUCTION

All-solid-state batteries are a promising alternative to lithium-ion batteries.<sup>1,2</sup> Higher achievable energy densities due to employment of different electrode materials and a reduced flammability risk of the solid electrolyte are desirable properties.<sup>2–4</sup> Different material classes were probed for employment as solid electrolytes (requiring ionic conductivities in the mS-range) including argyrodite,<sup>5–7</sup>  $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$  (LGPS)<sup>8</sup> and LGPS-type,<sup>9–12</sup> rare-earth halide materials,<sup>13–15</sup> and thio-LISICONs.<sup>16–18</sup> The latter were the key in finding the superionic conductor  $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ .<sup>8,19</sup>

Thio-LISICONs offer a great variety of iso- and aliovalent substitutions and therefore represent an important playground for understanding Li<sup>+</sup> transport. Prominently, three polymorphs  $\alpha$ ,  $\beta$ , and  $\gamma$  are formed within this material class crystallizing in the space groups  $\text{Cmcm}$ ,  $\text{Pnma}$ , and  $\text{Pmn}2_1$ , respectively.<sup>20–22</sup> The central nonlithium cation  $\text{Li}_y\text{MS}_4$  determines the  $(\text{PnS}_4)^{n-}$  ordering and therewith the polymorph, except for phosphorus where all three polymorphs are known.<sup>4,21</sup> For  $\text{Li}_3\text{PS}_4$ , the  $\gamma$ -polymorph exists at room temperature and the  $\beta$ -polymorph forms for temperatures above 543 K while the transition to the  $\alpha$ -polymorph happens

above 724 K.<sup>21</sup> The  $\alpha$ -polymorph could recently be stabilized at room temperature by rapid heating from  $\text{Li}_3\text{PS}_4$  glasses.<sup>23</sup> Forrester et al. were able to show by calculations that the  $(\text{PnS}_4)^{n-}$  polyhedra carry out librational motions depending on the polymorph. The  $\gamma$ -polymorph exhibits no librational motion, while the  $\alpha$ - and  $\beta$ -polymorphs perform different extents of librational motion.<sup>24</sup> The  $\gamma$ -polymorph is formed by pentavalent central cations  $\text{Li}_3\text{M}^{\text{V}}\text{S}_4$  ( $\text{M} = \text{P}, \text{Sb}, \text{As}$ ).  $\gamma\text{-Li}_3\text{PS}_4$ ,  $\text{Li}_3\text{AsS}_4$ , and  $\text{Li}_3\text{SbS}_4$  are reported to have low room-temperature conductivities of  $3 \times 10^{-7}$ ,<sup>25</sup>  $1.31 \times 10^{-5}$ ,<sup>26</sup> and  $4.8 \times 10^{-9} \text{ S}\cdot\text{cm}^{-1}$ , respectively.<sup>27</sup> A few iso- and aliovalent substitutions were performed for the  $\gamma$ -polymorph.<sup>26,28</sup> The substitution series  $\text{Li}_3\text{As}_{1-x}\text{Sb}_x\text{S}_4$  ( $0 \leq x \leq 1$ ) can be prepared as phase pure and an increase in unit cell volume can be observed for higher Sb contents. The best ionic conductivity

**Figure 1.** (a) Display of the typical  $(PnS_4)^{3-}$  arrangement, where all apexes of the tetrahedra point in the  $c$ -direction, of the  $\gamma$ - $Li_3PS_4$  polymorph. (b)  $(PnS_4)^{3-}$  tetrahedra are corner-sharing to the Li(1) site. (c) Second lithium site Li(2) is corner-sharing to the  $(PnS_4)^{3-}$  tetrahedra and to Li(1) site. This corner-sharing network depicts the  $Li_3SbS_4$  and  $Li_3Sb_{1-x}P_xS_4$  structure. (d) For the  $Li_{3+x}Sb_{1-x}Sn_xS_4$  substitution series, the additional Li<sup>+</sup> are placed onto the octahedral Li(3) interstitial site. Li(3) is edge-and face-sharing to Li(1) and Li(2) and just edge-sharing to  $(PnS_4)^{3-}$  tetrahedra.

for the unsubstituted material was  $3.2 \times 10^{-5} \text{ S}\cdot\text{cm}^{-1}$ .<sup>28</sup> In the  $Li_{3+x}As_{1-x}Ge_xS_4$  ( $0 \leq x \leq 0.5$ ) substitution series, the ionic conductivity increases from aforesaid  $1.31 \times 10^{-5} \text{ S}\cdot\text{cm}^{-1}$  to  $1.12 \times 10^{-3} \text{ S}\cdot\text{cm}^{-1}$  for  $Li_{3.334}As_{0.666}Ge_{0.334}S_4$  while keeping the  $\gamma$ -polymorph ( $Pmn2_1$ ).<sup>26</sup> Additionally, Al-Qawasmeh and Holzwarth stated that in the computed substitution series  $Li_{3+x}As_{1-x}Ge_xS_4$ , germanium reduces the migration energy for interstitial Li ions and vacancies.<sup>29</sup> The  $Li_{3-3x}Cu_{3x}SbS_4$  ( $0 \leq x \leq 1$ ) substitution series did not affect the ionic conductivity as long as the compounds crystallized in the orthorhombic space group.<sup>28</sup>

The crystal structure of the  $\gamma$ -polymorph consists of one tetrahedral pnictide site ( $PnS_4)^{3-}$ , having all tetrahedral apexes pointing in the  $c$ -direction (Figure 1a), and two tetrahedral Li<sup>+</sup> sites, Li(1) (Wyckoff 4b) and Li(2) (Wyckoff 2a) (Figure 1b,c). All tetrahedral sites together form a corner-sharing framework.<sup>21,27,29</sup> The  $Li_3SbS_4$  and the  $Li_3Sb_{1-x}P_xS_4$  substitution series crystallize in the same structure (Figure 1c). The introduction of excess Li<sup>+</sup> into the structure, e.g., for  $Li_{3+x}Sb_{1-x}Sn_xS_4$  substitution series, results in the occupation of an additional octahedral lattice site (Figure 1d), in accordance with the computationally proposed octahedral Li<sup>+</sup> position for  $Li_{3+x}As_{1-x}Ge_xS_4$ .<sup>29</sup>

Especially, the  $Li_{3+x}As_{1-x}Ge_xS_4$  substitution series emphasizes that good conductivities are achievable within the  $\gamma$ -polymorph ( $Pmn2_1$ ). However, the understanding of the Li<sup>+</sup> migration mechanism is limited. A migration mechanism involving a Li<sup>+</sup> interstitial site is expected to have the lowest activation barrier for this structure type.<sup>29,30</sup> In order to achieve a better understanding of this material class, the substitution series  $Li_3Sb_{1-x}P_xS_4$  ( $0 \leq x \leq 0.5$ ) and  $Li_{3+x}Sb_{1-x}Sn_xS_4$  ( $0 \leq x \leq 0.2$ ) are chosen to assess the impact

of both, an aliovalent and an isovalent substituent on the  $Li_3SbS_4$  structure. A combination of X-ray and neutron diffraction, impedance spectroscopy, and first-principles defect calculations shows the impact of several descriptors: (i) the Li<sup>+</sup> carrier density, (ii) the large size difference of Sb(+V) and P(+V), and (iii) the possibly changing Li<sup>+</sup> substructure<sup>16,31</sup> with the potential influence on ionic transport. The crystal structure of the solid electrolyte is impacted differently by P(+V) and Sn(+IV) substitution. In particular, the solubility limit of P(+V) is much higher in  $Li_3SbS_4$  compared to Sn(+IV) resulting in less pronounced geometrical changes in  $Li_{3+x}Sb_{1-x}Sn_xS_4$  in contrast to  $Li_3Sb_{1-x}P_xS_4$  substitution series. However, at the respective maximum solubility limits the ionic conductivities are comparable and both series can achieve increased ion transport properties of up to 4 orders of magnitude. The activation energy shows a correlation to the Li<sup>+</sup> carrier density in both substitution series. Together with the strong changes in ionic transport, this study suggests that the enhanced Li<sup>+</sup> motion is related to the changing defect formation energies. Overall, this work provides an overview and direct comparison of the impact of an aliovalent and an isovalent substitution in the thio-LISICON  $Li_3SbS_4$ .

## 2. EXPERIMENTAL SECTION

**2.1. Synthesis.** The syntheses were performed completely under an inert atmosphere. Both substitution series  $Li_3Sb_{1-x}P_xS_4$  ( $0 \leq x \leq 0.5$ ) and  $Li_{3+x}Sb_{1-x}Sn_xS_4$  ( $0 \leq x \leq 0.20$ ) were prepared mechanochemically followed by an annealing step. The starting materials  $Li_2S$  (Alfa Aesar, 99.9%), Sb (ChemPur, 99.999%), S (Acros Organics, 99.999%), and  $P_2S_5$  (Sigma-Aldrich, 99%), or Sn (ChemPur, 99.7%) were used in stoichiometric amounts with a slight excess of 4 mol %  $Li_2S$ . The mixtures were homogenized in an

agate mortar before transferring the powders into the ball mill cups. The powder-to-milling ratio was 1:30 with a milling media size of 5 mm. The samples were mechanochemically milled for 72 cycles at 360 rpm. One cycle consisted of 15 min of milling followed by a 5 min break. Subsequently, the powders were pressed into pellets and transferred into a carbon-coated and predried quartz ampule (800 °C for 2 h, dynamic vacuum). The ampules were sealed and the samples were annealed at 500 °C for 2 h in a tube furnace. Finally, samples were air-quenched and hand-ground for further characterization.

**2.2. X-ray Diffraction.** X-ray diffraction (XRD) measurements were carried out on a Stoe STADI P in Debye–Scherrer geometry with a Ge(111) monochromator and a Dectris MYTHEN2 1K detector, using Mo K<sub>α,1</sub> radiation ( $\lambda = 0.7093 \text{ \AA}$ ). The diffraction data were collected within a Q-range of 0.61–8.16 Å<sup>-1</sup>. The samples were prepared and sealed in borosilicate glass capillaries (Hilgenberg, Ø = 0.5 mm) under an inert atmosphere.

**2.3. Neutron Powder Diffraction.** Neutron powder diffraction data of both substitution series containing the natural abundant mixture of Li isotopes were collected at the Oak Ridge spallation neutron source (Oak Ridge National Laboratory). The POWGEN automatic sample changer at POWGEN (BL-11A beamline) was used. The samples (~3 g) were loaded under an inert atmosphere into a cylindrical vanadium can (Ø = 8 mm) which was sealed with a copper gasket to avoid air exposure during measurements. The data collection lasted 3.5 h per diffractogram in a high-resolution mode at room temperature using a single bank with a center wavelength of 1.5 Å.

**2.4. Rietveld Analysis.** Rietveld refinements were carried out on absorption-corrected neutron and laboratory XRD data using the TOPAS-Academic V6 software package.<sup>32</sup> For all substitutions, refinements of the neutron and laboratory X-ray data were performed. The structural parameters for Li<sub>3</sub>SbS<sub>4</sub> from Kimura et al. were used as a starting model for the refinement.<sup>27</sup> A convolution of pseudo-Voigt and GSAS back-to-back exponential functions was used to fit the profile shape of the neutron diffraction data.<sup>33</sup> The profile shape of the laboratory XRD data was fit with a Thompson–Cox–Hastings pseudo-Voigt function.<sup>34</sup> Initially the (1) background, (2) scale factors of main and side phases, (3) lattice parameter, and (4) the peak shape were refined. After a good fit of the profile was achieved, the (5) atomic coordinates, (6) occupancies, and (7) isotropic thermal displacements parameters were refined.

**2.5. Li<sub>3</sub>Sb<sub>1-x</sub>P<sub>x</sub>S<sub>4</sub>.** The refinements were carried out under the assumption that phosphorus replaces antimony on its site. Thus, the atomic coordinates and isotropic thermal displacement were constrained to be the same for phosphorus and antimony. Furthermore, the combined occupancy was constrained to unity. Additional Li<sup>+</sup> interstitial sites were probed for Li<sup>+</sup> occupancy, however, no meaningful values were obtained for occupancies and isotropic thermal displacements. Therefore, the occupancy of the initial lithium sites Li(1) and Li(2) was kept at unity. Finally, all parameters were refined together. The variables regarding Li<sup>+</sup> were globally refined from the neutron diffraction data, while the P/Sb-ratio was refined globally from the X-ray data. All residual variables were refined from both data sets.

**2.6. Li<sub>3+x</sub>Sb<sub>1-x</sub>Sn<sub>x</sub>S<sub>4</sub>.** The refinements were performed by replacing antimony with tin, therefore, the atomic coordinate and isotropic thermal displacement were constrained to be the same. The combined occupancy of antimony and tin was constrained to unity. Since the aliovalent substitution introduces more Li<sup>+</sup> into the structure, new Li<sup>+</sup> sites were explored. However, Li<sup>+</sup> could not be stabilized on any interstitial site. This is likely related to the observed asymmetric reflection shape of the (110) and (011) reflections with varying tin content (Figure S1). For the neutron measurement, several samples had to be synthesized to achieve about 3 g of the total sample amount, being necessary for the data acquisition and the reason for this left-side tailing. To keep the electroneutrality of the structure, additional Li<sup>+</sup> was placed on the octahedral interstitial Li(3).<sup>29</sup> This decision is based on the computed alloy of Li<sub>3</sub>AsS<sub>4</sub>–Li<sub>4</sub>GeS<sub>4</sub> which crystallizes in the same space group and introduces additional Li<sup>+</sup> into the crystal structure as well. Al-Qawasmeh et al.

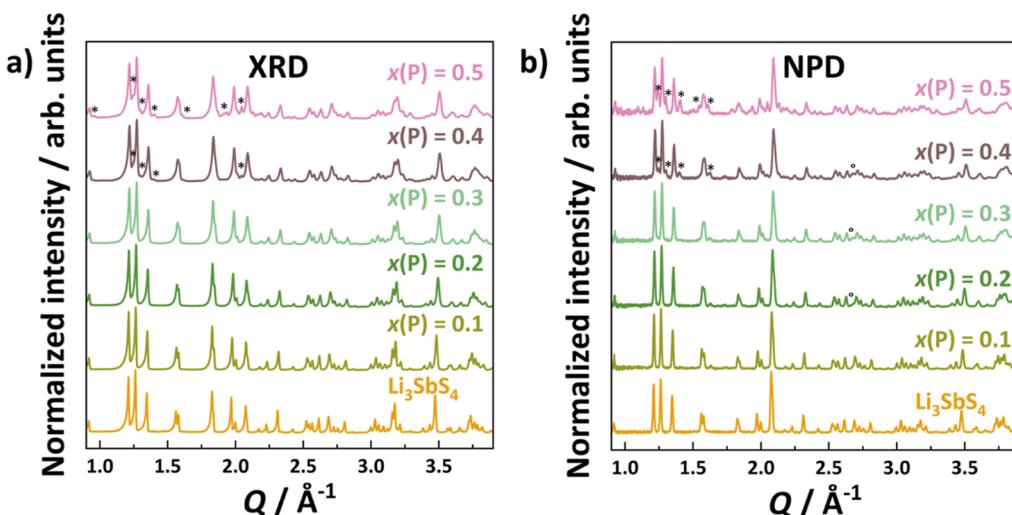

found that germanium stabilizes Li<sup>+</sup> on the additional site named “x”, which resembles the Li(3) site used here.<sup>29</sup> Additionally, <sup>6</sup>Li magic-angle spinning (MAS) nuclear magnetic resonance (NMR) spectra were collected for Li<sub>3.2</sub>Sn<sub>0.8</sub>Sb<sub>0.2</sub>S<sub>4</sub> confirming the interstitial Li(3) site (Figure S7). Moreover, for the observed Li<sub>4</sub>SnS<sub>4</sub> side phase, <sup>6</sup>Li MAS NMR measurements were conducted as well to exclude or pinpoint contribution to the peaks in the spectrum of Li<sub>3.2</sub>Sn<sub>0.8</sub>Sb<sub>0.2</sub>S<sub>4</sub>. The Li<sup>+</sup> occupancies of Li(1), Li(2), and Li(3) are freely refined within the Li<sup>+</sup> constraint; however, the occupancy of Li(1) and Li(2) always remained at unity for all samples. Thus, all additional Li<sup>+</sup> were placed onto the Li(3) site. It was possible to refine the atomic coordinates and the isotropic thermal displacement of Li(3) in the refinement process; however, it was not possible to open every variable concerning Li(3) at the end of the refinement for higher tin contents [ $x(\text{Sn}) \geq 0.15$ ]. All other parameters were refined together. The variables related to Li<sup>+</sup> and the Sb/Sn-ratio were refined globally from neutron diffraction data. For all other parameters, the X-ray and neutron diffraction data set were both taken into account.

VESTA was used to calculate polyhedral volumes.<sup>35</sup> The estimated standard deviation is shown as error bars in all data, except for the polyhedral volume uncertainties, which were calculated from bonds' distance uncertainties. For simplicity, the formula of a perfect tetrahedron or octahedron was used. All structural tables, crystallographic information files (CIFs), and used constraints (Figures S2–S4 and Tables S1–S12) can be found in the Supporting Information.

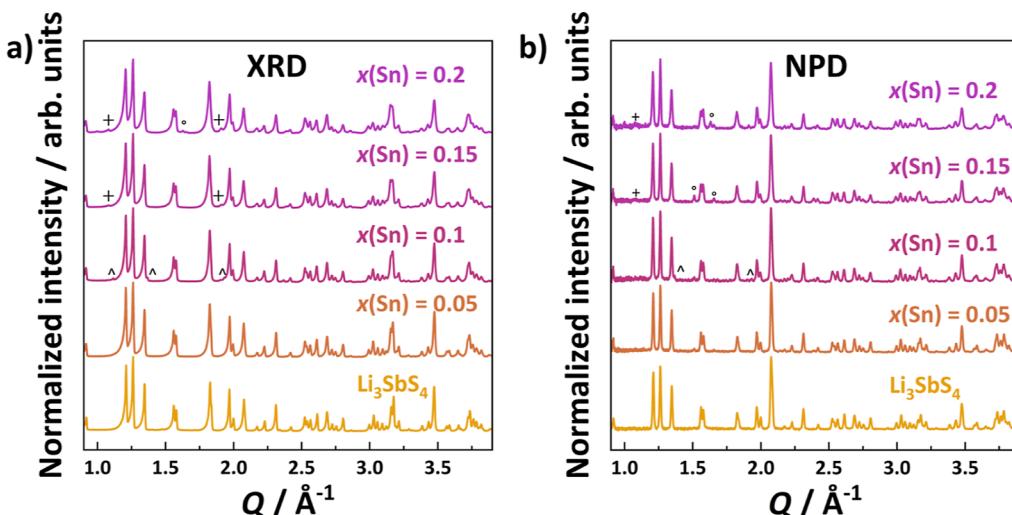

**2.7. Potentiostatic Electrochemical Impedance Spectroscopy.** Ionic conductivities were measured with AC impedance spectroscopy in a pouch cell setup. 150–200 mg of powders was isostatically pressed. The bore diameter was 32 mm. The pellets were pressed for 40 min at 3.98 kbar. The relative pellet densities are 74–83% for Li<sub>3+x</sub>Sb<sub>1-x</sub>Sn<sub>x</sub>S<sub>4</sub> and 80–88% for Li<sub>3</sub>Sb<sub>1-x</sub>P<sub>x</sub>S<sub>4</sub> (Table S13). Afterward, a circular gold layer was sputtered onto both sides of the pellet with a sputtering current of 30 mA for 300 s. The pressure in the sputter chamber was 0.05 mbar and the diameter of the circular gold layer was 8 mm. Lastly, the pellets were contacted to aluminum current collectors and sealed in pouch bags. The impedance measurements were carried out with a SP300 impedance analyzer (Biologic) in a temperature range of 298–333 K and in a frequency range of 7 MHz to 100 mHz with an amplitude of 30 mV. The impedance spectra were analyzed with RelaxIS (rhd instruments) software.

**2.8. Defect Formation Energy Calculations.** Using density functional theory (DFT), as implemented in the Vienna ab initio simulation package, the geometries of Li<sub>3</sub>PS<sub>4</sub>, Li<sub>3</sub>SbS<sub>4</sub>, and Li<sub>4</sub>SnS<sub>4</sub>, as well as all potentially stable phases of the ternary phase diagrams were relaxed (coordinates + shape + volume).<sup>36–38</sup> The Perdew–Burke–Ernzerhof<sup>39</sup> functional within the generalized gradient approximation (GGA), an energy convergence criterion of 10<sup>-6</sup> eV, a force cutoff of 10<sup>-3</sup> eV/Å for the unit cell relaxation and 10<sup>-2</sup> eV/Å for the other compounds of the phase diagram relaxations, and a Γ-centered *k*-point mesh of at least 7 points per Å<sup>-1</sup> were used. Wave functions were expanded as plane waves with an energy cutoff of 650 eV whereas core electrons were treated with the projector-augmented-wave potentials.<sup>40</sup> Input geometries and postprocessing were obtained with the pyCDT-package.<sup>41</sup> A 2 × 2 × 2 supercell was used for the defect calculations with an energy convergence criterion of 10<sup>-4</sup> eV, a force convergence criterion of 10<sup>-2</sup> eV/Å, and a Γ-centered *k*-point mesh of at least 4 points per Å<sup>-1</sup>. To avoid the common underestimation of band gaps by semilocal GGA functionals, the HSE06 hybrid functional was used.<sup>42</sup> Defect formation energies were corrected utilizing the methodology outlined by Freysoldt.<sup>43</sup>

**2.9. Nuclear Magnetic Resonance Spectroscopy.** Solid-state <sup>6</sup>Li MAS NMR spectra were recorded using a Bruker DSX 500 spectrometer equipped with a wide bore magnet ( $B_0 = 11.7 \text{ T}$ ,  $\nu_L = 73.6 \text{ MHz}$ ), with a 4 mm Bruker MAS probe. For Li<sub>4</sub>SnS<sub>4</sub>, single-pulse excitation experiment was performed using a π/2-pulse length of 7 μs at 100 W and a recycle delay of 5 s. For Li<sub>3.2</sub>Sn<sub>0.8</sub>Sb<sub>0.2</sub>S<sub>4</sub>, a quantitative spectrum was obtained with a short flip angle of π/12 (1.167 μs at 100 W) and a recycle delay of 10 s to ensure complete relaxation of all the components present. A spinning frequency of 12.5

**Figure 2.** Stacked (a) X-ray and (b) neutron diffractograms of the substitution series  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$ . For nominal substitution degrees larger than  $x(\text{P}) = 0.4$ , side phases are observable and can be assigned to  $\gamma$ - and  $\beta$ - $\text{Li}_3\text{PS}_4$  hinting at a solubility limit of  $\text{P}(+\text{V})$  in  $\text{Li}_3\text{SbS}_4$ . The  $\text{Li}_3\text{PS}_4$  side phases are marked with \*. Due to overlapping reflections, no distinction is made between the  $\gamma$ - and  $\beta$ -phase for simplicity, and just the most intense reflections of the  $\text{Li}_3\text{PS}_4$  polymorphs are marked. Additionally, an unknown side-phase reflection (marked with  $\circ$ ) can be seen in the neutron diffraction data, which is much less pronounced in the XRD patterns.

**Figure 3.** Stacked (a) X-ray and (b) neutron diffraction plots of  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  are shown up to  $x(\text{Sn}) = 0.2$ . The  $\text{Li}_{3.10}\text{Sb}_{0.90}\text{Sn}_{0.10}\text{S}_4$  sample has  $\text{Li}_3\text{SbS}_3$  marked with  $\wedge$  as an impurity. In the samples  $\text{Li}_{3.15}\text{Sb}_{0.85}\text{Sn}_{0.15}\text{S}_4$  and  $\text{Li}_{3.20}\text{Sb}_{0.80}\text{Sn}_{0.20}\text{S}_4$ ,  $\text{Li}_4\text{SnS}_4$  reflections are marked by + as impurities indicating a solubility limit. Reflections of an unknown side phase (marked with  $\circ$ ) are found in this substitution series.

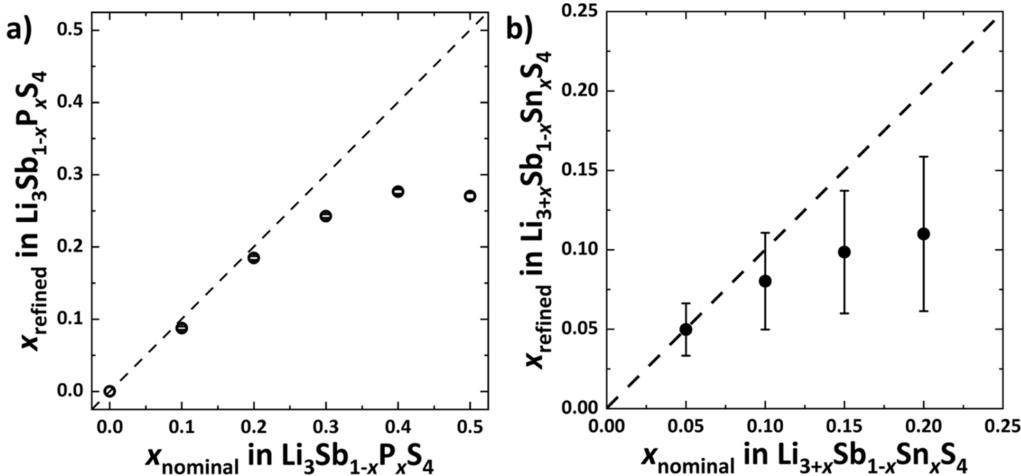

kHz was used for all samples. Fitting and deconvolution were performed using ssNake v1.4 software.

All samples were packed into 4 mm Zirconia rotors (inside glovebox;  $\text{H}_2\text{O} < 0.5 \text{ ppm}$ ,  $\text{O}_2 < 0.5 \text{ ppm}$ ) with single Vesel top cap and Teflon spacers to minimize moisture exposure during experiments. Magic-angle calibration was performed using the spinning sidebands of the  $^{23}\text{Na}$  resonance from solid  $\text{NaNO}_3$ . The  $^6\text{Li}$  chemical shift was referenced to the most intense signal of  $^6\text{Li}$ -enriched solid  $\text{CH}_3\text{COOLi}$  at 0 ppm.

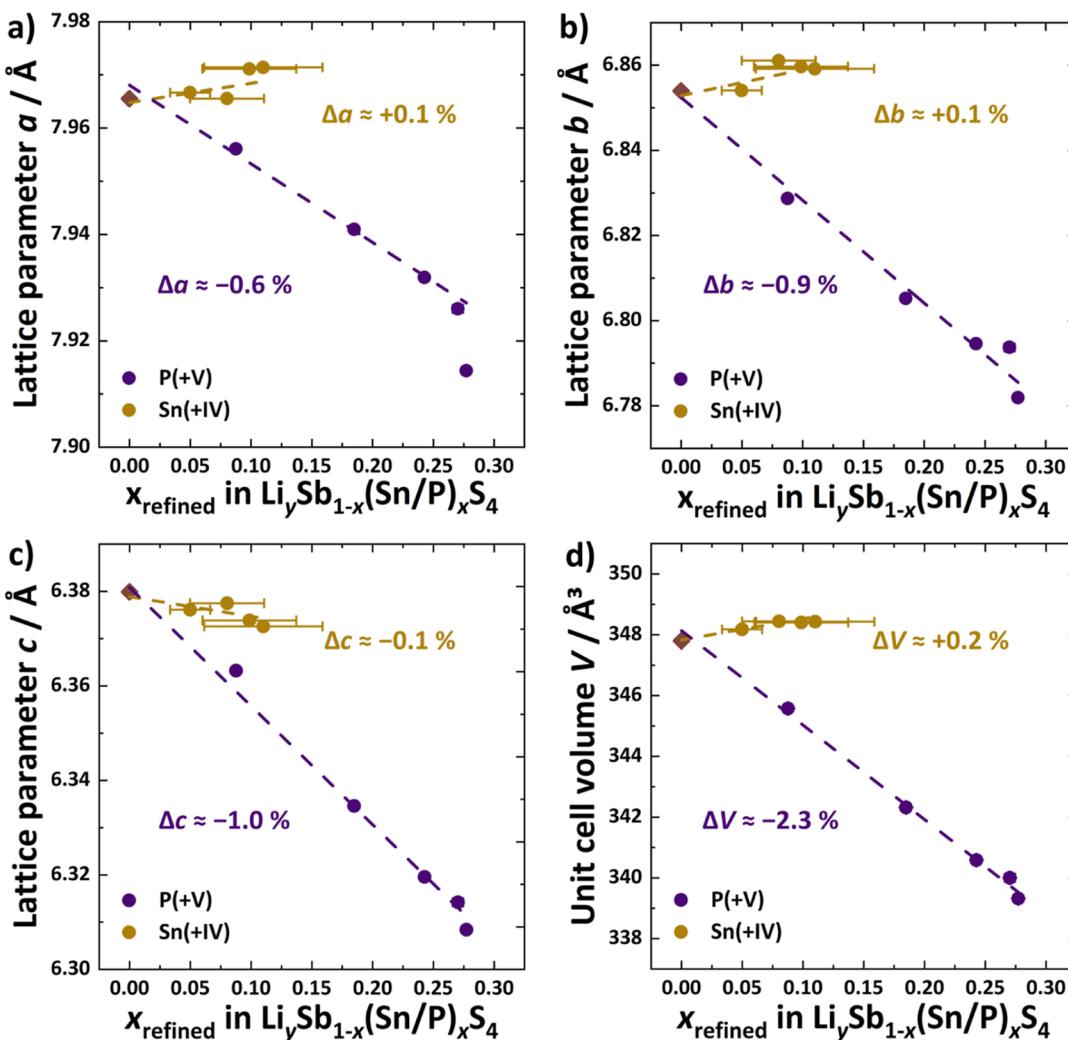

### 3. RESULTS AND DISCUSSION

**3.1. Synthesis and Solubility Limits.** The substitution series  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  and  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  were synthesized by the mechanochemical method with subsequent annealing and air-quenching. The phase purity is probed with XRD. Additional neutron diffraction data are collected to investigate the  $\text{Li}^+$  substructure. The X-ray and neutron diffraction patterns of  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  are shown in Figure 2.

The  $\text{P}(+\text{V})$  substitution of  $\text{Li}_3\text{SbS}_4$  crystallizes in the  $\gamma$ -polymorph over the investigated substitution range (Figure 2a).<sup>21</sup> The first additional reflections are observed for nominal composition larger than  $x(\text{P}) = 0.4$  belonging to the  $\gamma$ - and  $\beta$ - $\text{Li}_3\text{PS}_4$  polymorphs. In particular for  $\text{Li}_3\text{Sb}_{0.6}\text{P}_{0.4}\text{S}_4$ ,  $\gamma\text{-Li}_3\text{PS}_4$  [9.4(2) wt %] forms as a side phase, and for the  $\text{Li}_3\text{Sb}_{0.5}\text{P}_{0.5}\text{S}_4$ , a mixture of  $\gamma\text{-Li}_3\text{PS}_4$  [10.4(2) wt %] and  $\beta\text{-Li}_3\text{PS}_4$  [10.2(2) wt %] is observed. For simplicity, the  $\gamma$ - and  $\beta$ - $\text{Li}_3\text{PS}_4$  polymorph reflections are marked with the same symbols due to overlapping reflections from the high degree of similarity of the crystal structure because of similar lattice plane spacings. The formation of the  $\text{Li}_3\text{PS}_4$  structures hints at a solubility limit of around 30 at. % of  $\text{P}(+\text{V})$  on the  $\text{Sb}(+\text{V})$  site. Furthermore, the neutron diffraction patterns reveal an unknown side phase (Figure 2b), which is much less intense in the XRD pattern. Thus, the reflection must belong to a composition with elements that exhibit weak X-ray scattering

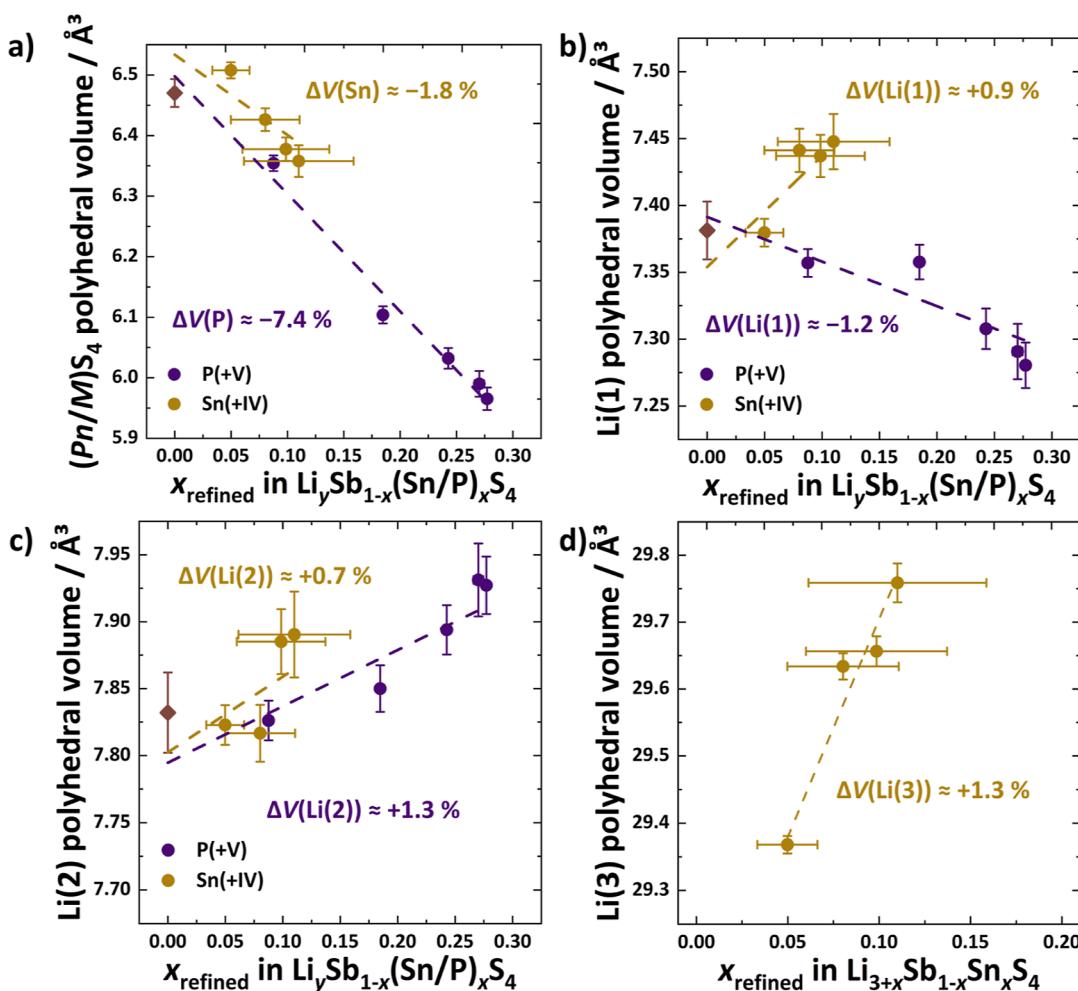

**Figure 4.** Trends in solubility of (a) P(+V) and (b) Sn(+IV) in  $\text{Li}_3\text{SbS}_4$ . A maximum content of 27 at. % of P(+V) on the Sb(1) site is found, while for Sn(+IV) a maximum of 11 at. % is found. The dashed lines indicate the perfect solubility.

**Figure 5.** (a) P(+V) substitution decreases lattice parameter  $a$  while the lattice parameter  $a$  increases for Sn(+IV) substitution. (b) Lattice parameter  $b$  increases for the Sn(+IV) substitution and decreases for the P(+V) substitution. (c) Lattice parameter  $c$  decreases for both substitution series. (d) P(+V) substitution shrinks the unit cell volume while the Sn(+IV) substitution enlarges the unit cell slightly. The  $y$ -errors are within the magnitude of the symbols for every plot. The dashed lines are guides to the eye.

form factors, but it could not be assigned to any specific phase as just one impurity reflection is observed.

The aliovalent Sn(+IV) substitution series is synthesized up to a nominal content of 20 at. % Sn(+IV) on the Sb(+V) site

**Figure 6.** (a) Display of the decrease in  $(Pn/M)\text{S}_4$  polyhedron volume for P(+V) substitution and Sn(+IV) substitution in  $\text{Li}_3\text{SbS}_4$ . (b) Li(1) tetrahedron volume increases for Sn(+IV) substitution and decreases for the P(+V) substitution. (c) Li(2) polyhedron volume increases for both substitution series. (d) Li(3) octahedron volume increases for higher Sn(+IV) content. The dashed lines are guides to the eye.

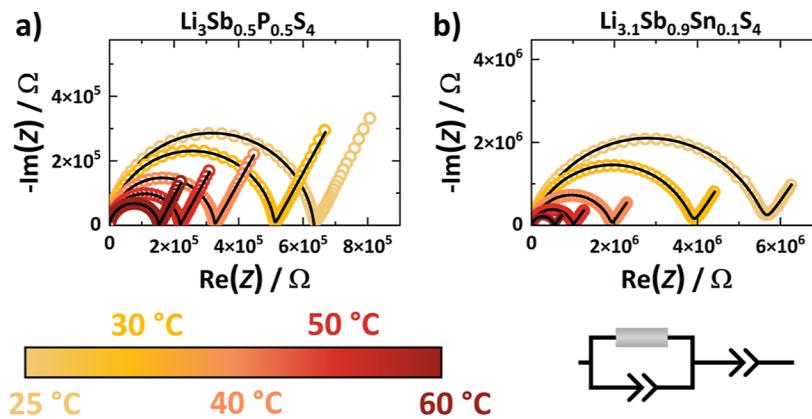

(Figure 3). Similar to the P(+V) substitution, the Sn(+IV) substitution crystallizes in the  $\gamma$ -polymorph over the investigated substitution range (Figure 3a). For nominal contents of more than  $x(\text{Sn}) = 10$  at. %, side phases can be observed. The  $\text{Li}_{3.10}\text{Sb}_{0.90}\text{Sn}_{0.10}\text{S}_4$  samples contain  $\text{Li}_3\text{SbS}_3$  (2.84(5) wt %) as a side phase (Figure 3a), where loss of sulfur during the reaction can be the reason for the development of this impurity. The diffraction patterns of the two highest tin content phases of 15 and 20 at. % indicate the presence of  $\text{Li}_4\text{SnS}_4$  as the secondary phase, containing 4.8(1) and 9.8(1) wt %, respectively. This implies a solubility limit of 10 at. % of Sn(+IV) in  $\text{Li}_3\text{SbS}_4$ . Some additional reflections can be observed in neutron diffraction and XRD patterns which cannot be assigned to any specific phase. The solubility limits, which are estimated from the diffraction patterns, are in accordance with the Rietveld refinement results (Figure 4).

Besides the large radius difference of  $0.33 \text{ \AA}$ ,<sup>44,45</sup> P(+V) can be incorporated up to 27(1) at. % on the Sb(+V) site, based on the Rietveld refinements. The radius similarity of Sn(+IV) ( $0.55 \text{ \AA}$ )<sup>44</sup> and Sb(+V) ( $0.50 \text{ \AA}$ )<sup>45</sup> in tetrahedral coordination would suggest a higher solubility limit than P(+V) but just up to 11(4) at. % of Sn(+IV) can be incorporated into the  $\text{Li}_3\text{SbS}_4$  structure. The lower solubility limit of Sn(+IV) compared to P(+V) could stem from the preference of Sn(+IV) to form  $\text{Li}_4\text{SnS}_4$  in the  $\beta$ -polymorph.<sup>16</sup> From now on, the unit cell

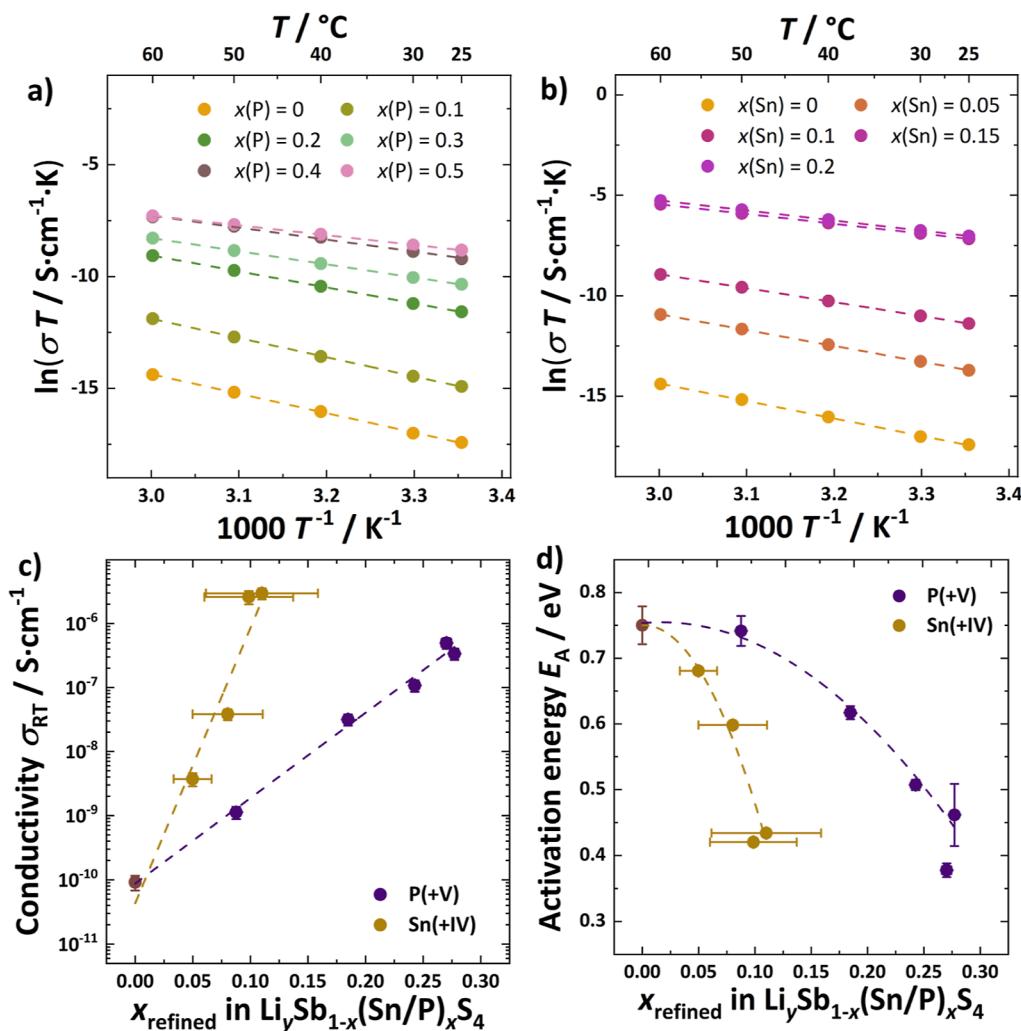

parameters and polyhedra volumes are displayed against the refined P(+V)/Sn(+IV) content to depict reality more accurately.

**3.2. Unit Cell and Polyhedra Changes.** By evaluation of the X-ray and neutron diffractograms with Rietveld refinements, the geometrical adaptions of the  $\text{Li}_3\text{SbS}_4$  structure upon P(+V) and Sn(+IV) substitution are monitored. First, the lattice parameter  $a$ ,  $b$ , and  $c$  as well as the unit cell volume  $V$  are determined (Figure 5) and changes are given as percentage values to better assess the magnitude of total structural changes.

The P(+V) substitution in  $\text{Li}_3\text{SbS}_4$  leads to a decrease of all lattice parameters, where  $a$ ,  $b$ , and  $c$  reduce about 0.6, 0.9, and 1.0%, respectively. In contrast, the introduction of Sn(+IV) in  $\text{Li}_3\text{SbS}_4$  leads to a slight increase in lattice parameter  $a$  (0.1%) and lattice parameter  $b$  (0.1%) while lattice parameter  $c$  is decreased (0.1%). The overall unit cell volume shrinks for the P(+V) substitution by about 2.3% and enlarges for the Sn(+IV) substitution by about 0.2% (Figure 5d). However, keep in mind that the smaller changes of Sn(+IV) compared to P(+V) can be reasoned by the lower solubility of Sn(+IV) in the  $\text{Li}_3\text{SbS}_4$  structure. In addition, the similar radius size of Sn(+IV) and Sb(+V) may also diminish the extent of structural changes. The  $(\text{Sb}_{1-x}\text{P}_x\text{S}_4)^{3-}$  tetrahedron volume shrinks by about 7.4% upon P(+V) incorporation (Figure 6a), while the

**Figure 7.** Exemplary temperature-dependent impedance spectra of (a) nominal composition  $\text{Li}_3\text{Sb}_{0.5}\text{P}_{0.5}\text{S}_4$  and (b) nominal composition  $\text{Li}_{3.1}\text{Sb}_{0.9}\text{Sn}_{0.1}\text{S}_4$ . The solid lines represent actual fits. Nonfitted data points were excluded with the Kramers–Kronig relationship.

**Figure 8.** Arrhenius plots of the substitution series (a)  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  and (b)  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  showing the expected linear behavior in the investigated temperature range. The description in (a,b) refers to nominal compositions. (c) Room-temperature conductivity  $\sigma_{\text{RT}}$  of both substitution series shows a linear increase with higher substituent content in the crystal structure. (d) Activation energy  $E_A$  decreases with higher P(+V) and Sn(+IV) content to roughly the same value for the highest substitution degree. The dashed lines in (a,b) are actual fits, while the dashed lines in (c,d) are guides to the eye.

$(\text{Sb}_{1-x}\text{Sn}_x\text{S}_4)^{(3-x)-}$  tetrahedron volume is reduced by about 1.8% upon Sn(+IV) introduction. For the P(+V) substitution, a decrease in tetrahedron volume is expected, however, the decreasing  $(\text{Sb}_{1-x}\text{Sn}_x\text{S}_4)^{(3-x)-}$  volume seems rather unex-

pected. In particular, Sn(+IV) ( $r = 0.55 \text{ \AA}$ )<sup>44</sup> and Sb(+V) ( $r = 0.50 \text{ \AA}$ )<sup>45</sup> in tetrahedral coordination are similar in size and Sn(+IV) has a lower valence than Sb(+V). On the basis of a purely Coulombic argument, the electrostatic attraction

between Sn–S should be lower than Sb–S, resulting in longer bonds. Additionally, the magnitude of the wavenumbers of the  $(\text{SnS}_4)^{4-}$  and  $(\text{SbS}_4)^{3-}$  stretching modes in Raman gives insights about the bond strength as the force constant can be estimated.<sup>46</sup> The symmetric stretching mode of  $(\text{SnS}_4)^{4-}$  and  $(\text{SbS}_4)^{3-}$  is expected at  $\sim 345$  and  $\sim 360 \text{ cm}^{-1}$ , respectively.<sup>27,46–48</sup> A smaller wavenumber corresponds to a smaller force constant,<sup>46</sup> hence the Sn–S bond should also be longer than Sb–S in terms of covalent bonding. Therefore, the reduction of  $(\text{Sb}_{1-x}\text{Sn}_x\text{S}_4)^{(3-x)-}$  volume might be rather related to the additional number of  $\text{Li}^+$  in the structure.

For the  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  substitution series, the Li(1) tetrahedron volume decreases by about 1.2% and the Li(2) tetrahedron volume increases by about 1.3% (Figure 6b,c). The  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  substitution series depicts an expansion in Li(1) (0.9%) and in Li(2) (0.7%) tetrahedron volume (Figure 6b,c). Additionally, the Li(3) octahedron enlarges with higher Sn(+IV) contents (Figure 6d). The very minor unit cell expansion for the Sn(+IV) substitution seems to be driven by the  $\text{Li}^+$  substructure, as the volume of  $(\text{Sb}_{1-x}\text{Sn}_x\text{S}_4)^{(3-x)-}$  tetrahedron, the only nonlithium cation site, reduces and all occupied lithium polyhedra are expanding in size. Furthermore, the unit cell shrinkage of the P(+V) substitution shows mixed volume changes for the  $\text{Li}^+$  polyhedra, which prevents us to identify the main driving factor of the overall unit cell volume reduction.

**3.3. Ionic Transport.** Changes in ionic transport were probed with temperature-dependent potentiostatic impedance spectroscopy. Exemplary impedance responses and their fits are shown in Figure 7. The Nyquist plots of the other compositions can be found in Supporting Information (Figures S5 and S6).

The compositions of  $\text{Li}_3\text{SbS}_4$  and lower substitution degrees are highly resistive, hence the monitored temperature range is 25–60 °C. At lower temperatures, the semicircles cannot be as nicely resolved as the semicircles at room temperature (Figures S5 and S6). The impedance spectra are fit with equivalent circuits depending on the observed features. For the more resistive samples, a resistor in parallel to a constant-phase element (CPE) is used because just a semicircle is observable. The better-conducting samples exhibit a semicircle and the blocking tail of the gold electrodes; thus, the impedance spectra are fit with a resistor in parallel to a CPE in series with a CPE (Figure 7). As it is indicative in Figure 7a, the impedance spectra of  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  show suppressed semicircles, which is also reflected in the  $\alpha$ -values ranging from 0.82 to 0.95 and capacitances ranging between  $8 \times 10^{-11}$  and  $1 \times 10^{-10} \text{ F}$ . The substitution series  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  exhibits  $\alpha$ -values of 0.85 to 0.93 and lower capacitances between  $3 \times 10^{-11}$  and  $8 \times 10^{-11} \text{ F}$ . The nonideal  $\alpha$ -values and capacitances for both substitution series hint at a mixture of in-grain diffusion and transport across grain boundaries.<sup>49,50</sup> Thus, the reported values correspond to total conductivity values. Both substitution series exhibit Arrhenius-like behavior over the monitored temperature range (Figure 8a,b).

The room-temperature conductivity of  $\text{Li}_3\text{SbS}_4$  is determined to be  $9.2(7) \times 10^{-11} \text{ S} \cdot \text{cm}^{-1}$  (Figure 8), which is nearly 2 orders of magnitude lower than the value of  $4.8 \times 10^{-9} \text{ S} \cdot \text{cm}^{-1}$  (25 °C) reported by Kimura et al.<sup>27</sup> In addition, Matsuda et al. reported an ionic conductivity of  $\text{Li}_3\text{SbS}_4$  synthesized by an ion-exchange process of  $8.5 \times 10^{-8} \text{ S} \cdot \text{cm}^{-1}$  (50 °C), being 2 orders of magnitude higher than the herein-found conductivity at 50 °C of  $\text{Li}_3\text{SbS}_4$ .<sup>51</sup> Furthermore, Huber et al. report an

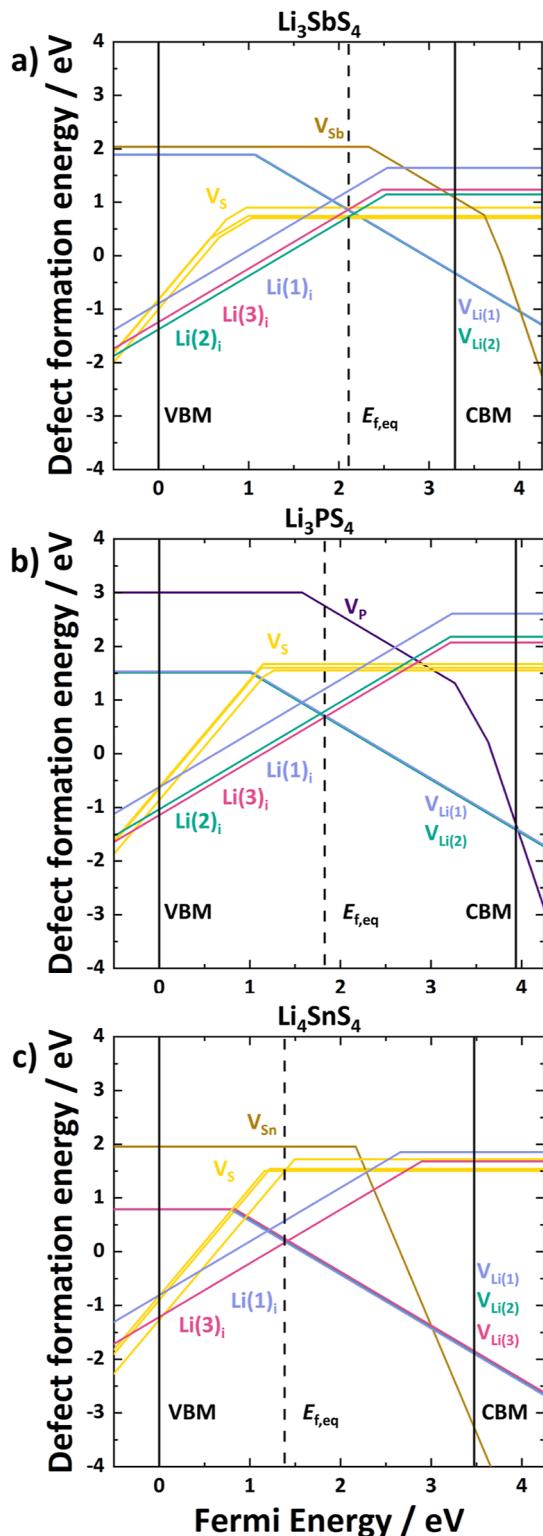

ionic conductivity of  $3.2 \times 10^{-7} \text{ S} \cdot \text{cm}^{-1}$  (267 °C) for  $\text{Li}_3\text{SbS}_4$  synthesized by a solid-state synthesis.<sup>52</sup> Hence, the synthesis procedure most likely influences the resulting ionic conductivity.<sup>53,54</sup>

The room-temperature conductivity increases for both substituents (Figure 8c). However, the Sn(+IV) substitution leads to a 3-fold faster increase in ionic conductivity than the P(+V) substitution. The highest obtained room-temperature ionic conductivity values are  $2.9(2) \times 10^{-6} \text{ S} \cdot \text{cm}^{-1}$  for  $\text{Li}_{3,2}\text{Sb}_{0,8}\text{Sn}_{0,2}\text{S}_4$  and  $4.9(9) \times 10^{-7} \text{ S} \cdot \text{cm}^{-1}$  for  $\text{Li}_3\text{Sb}_{0,5}\text{P}_{0,5}\text{S}_4$ , which are 5 and 4 orders of magnitude higher than the conductivity of  $\text{Li}_3\text{SbS}_4$ , respectively. The activation energy reflects the opposite trend to the conductivity and is reduced to 0.37(1) and 0.43(1) eV for the P(+V) substitution and the Sn(+IV) substitution, respectively. In addition, the decrease in activation energy appears steeper for the Sn(+IV) than the P(+V) substitution, albeit both substitution series reach comparable activation energies for their highest substitution content. For higher substitution degrees, side phases with up to  $\sim 20$  wt % for P(+V) and up to  $\sim 10$  wt % for Sn(+IV) substitution form, possibly influencing the ionic conductivity. For the  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  side phases, such as  $\gamma$ - and  $\beta$ - $\text{Li}_3\text{PS}_4$  are observed and for  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$ , only  $\text{Li}_4\text{SnS}_4$  is observed.  $\beta$ - $\text{Li}_3\text{PS}_4$  and  $\gamma$ - $\text{Li}_3\text{PS}_4$  have room-temperature conductivities of  $\sim 9 \times 10^{-7}$  and  $3 \times 10^{-7} \text{ S} \cdot \text{cm}^{-1}$ , respectively.<sup>21,25,55</sup> The reported  $\text{Li}_4\text{SnS}_4$  conductivity values range between  $10^{-6}$  and  $10^{-5} \text{ S} \cdot \text{cm}^{-1}$ .<sup>56–59</sup> Both solid solution series reached for their highest substitution degree of the ionic conductivity of the other end member, being  $\text{Li}_3\text{PS}_4$  and  $\text{Li}_4\text{SnS}_4$ , thus no significant influence in the measured conductivity can be linked to the side phases in the investigated substitution range. Nevertheless, as soon as the phase mixture mainly consists of the side phases, namely  $\text{Li}_3\text{PS}_4$  or  $\text{Li}_4\text{SnS}_4$ , these will impact the measured ionic conductivity directly. Overall, both substituents show a positive impact on  $\text{Li}^+$  transport in the  $\text{Li}_3\text{SbS}_4$  structure, where the aliovalent Sn(+IV) substitution enhances the  $\text{Li}^+$  motion more efficiently than the isovalent P(+V) substitution.

**3.4. Defect Formation Energies.** To assess whether diffusion of  $\text{Li}^+$  vacancies or  $\text{Li}^+$  interstitials is dominating, defect formation energies were computed with DFT calculations. The formation of a variety of defects is possible in both the aliovalent  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  and isovalent  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  substitution series. However, which defects form, is preferably determined by the energy landscape, in particular the local bonding environment of a crystal system, which is influenced by the composition.<sup>54</sup>

Using the Kröger–Vink notation, a wide variety of defects is explored for each end member of the substitution series, e.g.,  $\text{Li}_3\text{SbS}_4$ ,  $\text{Li}_3\text{PS}_4$ , and  $\text{Li}_4\text{SnS}_4$  such as  $\text{Li}^+$  interstitials ( $\text{Li}_i^\bullet$ ),  $\text{Li}^+$  vacancies ( $\text{V}_{\text{Li}}'$ ), sulfur vacancies ( $\text{V}_S^{••}$ ), and  $\text{Sb}(+V)/\text{P}(+V)/\text{Sn}(+IV)$  vacancies ( $\text{V}_{\text{Sb/P}}^{''''''}$  and  $\text{V}_{\text{Sn}}^{''''''}$ ). To allow for a direct comparison, the defect formation energy calculations of  $\text{Li}_4\text{SnS}_4$  were performed assuming that  $\text{Li}_4\text{SnS}_4$  crystallizes in the  $\gamma$ - $\text{Li}_3\text{PS}_4$  structure, as  $\text{Li}_3\text{SbS}_4$  does, and not in the experimentally found  $\beta$ - $\text{Li}_3\text{PS}_4$  modification.<sup>16,59</sup> The calculated defect formation energies with respect to the Fermi energy are shown in Figure 9.

The equilibrium Fermi level  $E_{\text{f},\text{eq}}$  decreases from  $\text{Li}_3\text{SbS}_4$  (2.11 eV) over  $\text{Li}_3\text{PS}_4$  (1.83 eV) to  $\text{Li}_4\text{SnS}_4$  (1.38 eV), which is pinned by  $\text{Li}_i^\bullet$  and  $\text{V}_{\text{Li}}'$ . At the  $E_{\text{f},\text{eq}}$  within all three end members, defects with lower charges, namely  $\text{Li}_i^\bullet$  and  $\text{V}_{\text{Li}}'$ , form easily than the higher charged defects, namely  $\text{V}_S^{••}$ ,

**Figure 9.** Defect formation energies of (a)  $\text{Li}_3\text{SbS}_4$ , (b)  $\text{Li}_3\text{PS}_4$ , and (c)  $\text{Li}_4\text{SnS}_4$ . The compositions are computed within the phase regions of  $\text{Li}_2\text{S}-\text{Li}_3\text{SbS}_4-\text{S}$ ,  $\text{Li}_2\text{S}-\text{Li}_3\text{PS}_4-\text{S}$ , or  $\text{Li}_2\text{S}-\text{Li}_4\text{SnS}_4-\text{S}$ . The dashed line corresponds to the equilibrium Fermi level  $E_{f,\text{eq}}$  where the charge sum of all the defects is zero, and the solid lines are the valence band maximum and conduction band minimum spanning the band gap of each bulk material.

$V_{\text{Sb}/\text{P}}^{''''}$ , and  $V_{\text{Sn}}^{''''}$ . The majority of charge carrier seems to be  $\text{Li}_i^{\bullet}$  and  $\text{V}_{\text{Li}}'$  in every case when comparing the relative

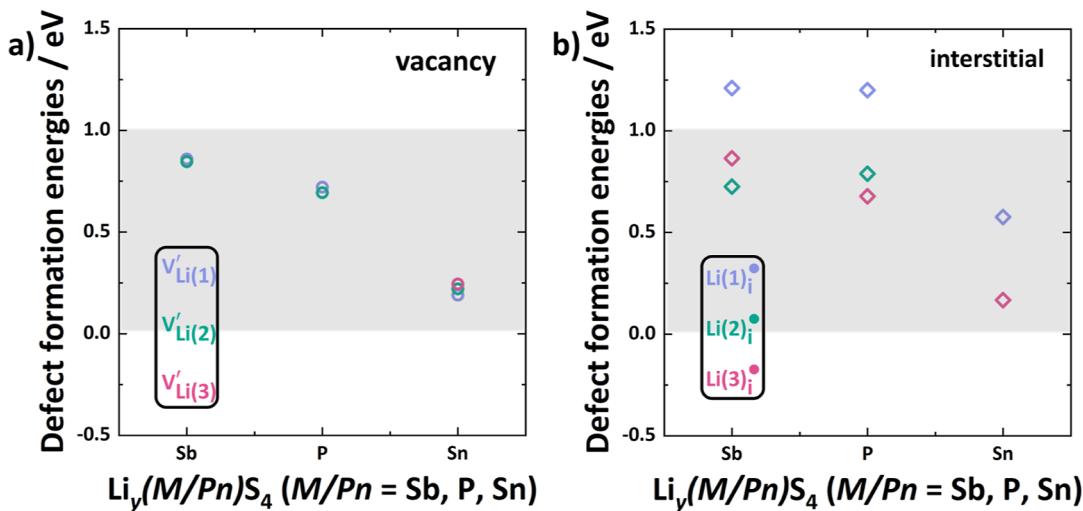

energetic position of  $\text{Li}_i^{\bullet}$  and  $\text{V}_{\text{Li}}'$ . Furthermore, when changing the composition from  $\text{Li}_3\text{SbS}_4$  to  $\text{Li}_3\text{PS}_4$  or  $\text{Li}_4\text{SnS}_4$ , the formation energies of  $\text{Li}_i^{\bullet}$  and  $\text{V}_{\text{Li}}'$  are reduced in both cases (Figure 10).

The vacancy formation on the  $\text{Li}^+$  sites in  $\text{Li}_3\text{SbS}_4$  requires an energy of about  $\sim 0.85$  eV, while for  $\gamma\text{-Li}_3\text{PS}_4$  and  $\text{Li}_4\text{SnS}_4$   $\sim 0.71$  and  $\sim 0.21$  eV are necessary, respectively (Figure 10a). In relative changes, the P(+V) and Sn(+IV) substitutions reduce the vacancy formation energy by 16 and 75%, respectively. In addition, the interstitial formation energy varies more within one compound than the formation energy of the vacancies (Figure 10b). The formation energy of interstitials ranges from 0.87 to 1.21 eV ( $\text{Li}_3\text{SbS}_4$ ), 0.68 to 1.20 eV ( $\gamma\text{-Li}_3\text{PS}_4$ ), and 0.17 to 0.58 eV ( $\text{Li}_4\text{SnS}_4$ ). While in  $\text{Li}_4\text{SnS}_4$  the  $\text{Li}^+$  interstitial formation is significantly reduced, for  $\gamma\text{-Li}_3\text{PS}_4$ , it is similar to  $\text{Li}_3\text{SbS}_4$ . The smaller overall reduction in defect formation energy for  $\gamma\text{-Li}_3\text{PS}_4$  compared to  $\text{Li}_4\text{SnS}_4$  may be connected to the different inclines in conductivity improvement.

Lepley et al. reported relative formation energies of  $\text{Li}^+$  vacancies and  $\text{Li}^+$  interstitials for  $\gamma\text{-Li}_3\text{PS}_4$ . The relative vacancy formation energy of the  $\text{Li}(1)$  site is  $-0.04$  eV with regard to the formation energy of a vacancy in the  $\text{Li}(2)$  site, while the herein-found vacancy formation energies differ about  $0.03$  eV. The interstitial formation energies are calculated relative to the  $\text{Li}(3)_i^{\bullet}$  (set to 0 eV) and are  $0.44$  eV for  $\text{Li}(1)_i^{\bullet}$  or 0 eV for  $\text{Li}(2)_i^{\bullet}$ .<sup>60</sup> Yang et al. determined the interstitial formation energies relative to  $\text{Li}(3)_i^{\bullet}$  (set to 0 eV) finding  $0.51$  eV for  $\text{Li}(1)_i^{\bullet}$  and  $0.12$  eV for  $\text{Li}(2)_i^{\bullet}$ .<sup>30</sup> Thus, the studies of Lepley et al.<sup>60</sup> and Yang et al.<sup>30</sup> are both agreeing that  $\text{Li}(1)_i^{\bullet}$  has the highest defect formation energy of the interstitials, which is also found here. Moreover, the relative interstitial formation energies found herein are similar to Yang et al.,<sup>30</sup> being  $0.52$  eV ( $\text{Li}(1)_i^{\bullet}$ ),  $0.11$  eV ( $\text{Li}(2)_i^{\bullet}$ ), and  $0$  eV ( $\text{Li}(3)_i^{\bullet}$ ), whereas the energies are referenced to  $\text{Li}(3)_i^{\bullet}$ .

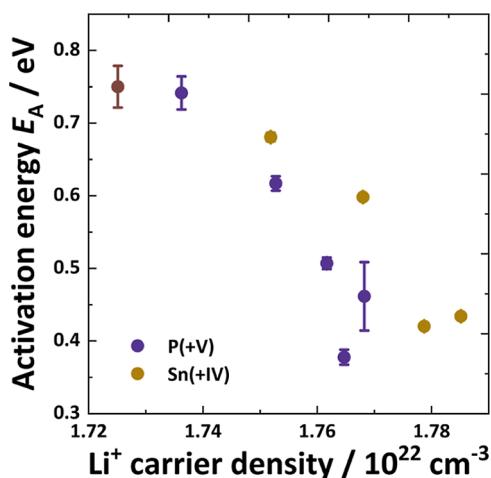

Yang et al. determined different paths for  $\text{Li}^+$  interstitial and vacancy diffusion in every unit cell direction for  $\gamma\text{-Li}_3\text{PS}_4$ , thereby finding that the direct hopping mechanism along the  $c$ -direction has the lowest energy barrier of  $0.16$  eV per ion jump. In addition, the vacancy diffusion barrier in the  $c$ -direction is determined to be  $0.26$  eV requiring almost double the energy than the easiest  $\text{Li}^+$  interstitial mechanism in the same direction. Al-Qawasmeh et al. state that an interstitial or interstitialcy mechanisms for carrier migration might be more likely within the solid solution of  $\text{Li}_{3+x}\text{As}_{1-x}\text{Ge}_x\text{S}_4$  (crystallizing also in the  $\gamma$ -polymorph) than a vacancy mechanism as the additional  $\text{Li}^+$  already contribute to the interstitial population and some vacancy sites close to Ge sites are relatively unstable limiting the vacancy pathways. In addition, the introduction of tetravalent Ge adjusts the relative site energies of the  $\text{Li}^+$  positions reducing the migration energy in solid solutions.<sup>29</sup> Hence, the substituents P(+V) and Sn(+IV) are expected to modify the energy landscape of the solid electrolyte, which in turn should facilitate  $\text{Li}^+$  interstitial or vacancy transport.

In general, the computed defect formation energies are in line with the observed  $\text{Li}^+$  transport as both substituents promote  $\text{Li}^+$  motion. The 3-fold faster increase in  $\text{Li}^+$  conductivity for  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  compared to  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  is reasoned with the stronger decrease in  $\text{Li}_i^{\bullet}$  and  $\text{V}_{\text{Li}}'$  formation energies at the  $E_{f,\text{eq}}$ . The assumption has to be made that either all or a major part of the generated interstitials and vacancies contribute to the ionic transport. Looking at the  $\text{Li}^+$  carrier density, being calculated as the refined number of  $\text{Li}^+$  divided

**Figure 10.** Comparison of the (a)  $V'_{\text{Li}}$  and (b)  $\text{Li}_i^*$  formation energies at the  $E_{f,\text{eq}}$  for the different compositions. The gray beam is a visual reference for comparing the energies of (a,b).

by unit cell volume, can be indirectly insightful in terms of  $\text{Li}^+$  transport. The activation energy is found to decrease for higher  $\text{Li}^+$  carrier densities (Figure 11).

**Figure 11.** Correlation between  $\text{Li}^+$  carrier density, estimated from the number of  $\text{Li}^+$  in the unit cell and the unit cell volume, and activation energy showing a decrease of migration barrier upon increase in  $\text{Li}^+$  carrier density.

As the energy landscape on which the  $\text{Li}^+$  distribute and move on is normally created by the anionic framework and its modulation is related to changes in the host-framework, the connection of activation energy and  $\text{Li}^+$  carrier density does not seem to be straightforward. However, the overall activation energy consists of the migration energy  $E_m$  and the defect formation energy  $\Delta H_f$ .

$$E_A = E_m + \frac{\Delta H_f}{2}$$

The migration energy  $E_m$  is essentially the energy to move a  $\text{Li}^+$  to another crystal site while the  $\Delta H_f$  takes into account formation to create a defect. In both substitution series, the activation energy is strongly reduced and  $\text{Li}^+$  transport significantly improved. On the one hand, the introduction of Sn(+IV) and P(+V) should modify the energy landscape and

in the best case result in the occupancy of more  $\text{Li}^+$  sites to obtain a more extensive and disordered  $\text{Li}^+$  substructure. Nevertheless, this is not observed in this study. On the other hand, the starting material  $\text{Li}_3\text{SbS}_4$  has an ionic conductivity of  $9.2(7) \times 10^{-11} \text{ S}\cdot\text{cm}^{-1}$  at room temperature, being basically non- $\text{Li}^+$  conducting. The latter enforces the formation of defects for ion conduction. This might be simplified by having a higher  $\text{Li}^+$  density in the unit cell. Statistically, the more  $\text{Li}^+$  in the structure the higher the probability of forming a defect.

The number of defects are clearly linked to the synthesis procedure (and conditions) and composition of the materials.<sup>54,61</sup> As all compositions are synthesized similarly, the thermally generated defects should be comparable, hence the change in defect formation energy is more likely related to the altered composition as the defect formation energy is a function of the lithium chemical potential.<sup>54,62</sup> After all, the defect formation energy might be the strongest influence as these systems are not superionic conductors. Thus, the defect formation energy cannot be neglected anymore as charge carrier are not readily available and have to be created first.<sup>63,64</sup>

#### 4. CONCLUSION

In this work, the substitution series  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  and  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  were synthesized and the influence of the substitutions on the structure and transport was investigated. The solubility limit seems to be influenced by geometric restrictions (P(+V)) and by the preference for the  $\beta$ -polymorph (Sn(+IV)). The geometric changes for Sn(+IV) are negligible, while P(+V) shows slightly more pronounced polyhedron and unit cell volume changes, however, no strong trends were observable. Both substitution series promote ionic transport of  $\text{Li}_3\text{SbS}_4$  significantly by up to 4 orders of magnitude. Neither can be related to a better connection in the  $\text{Li}^+$  substructure or an opening of a diffusion bottleneck. A 3-fold faster increase of Li-ion transport for  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  compared to  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  appeared puzzling as geometrical influences on  $\text{Li}^+$  transport can be eliminated. Overall, the  $\text{Li}^+$  carrier density might indirectly reflect changes in defect formation energy. The calculated defect formation energies depend on the chemical composition and are decreased upon the substitution of Sn(+IV) and P(+V). This work shows that the defect formation energy can influence the  $\text{Li}^+$  transport

strongly and cannot be neglected in the case of the investigated thio-LISICON substitutions series. Additionally, it emphasizes that the choice and combination of elements are a decisive factor on the ionic conductivity by determining the magnitude of defect formation energy.
